0.2.5 BucketSort Time Analysis

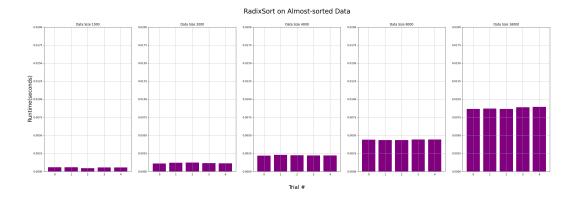

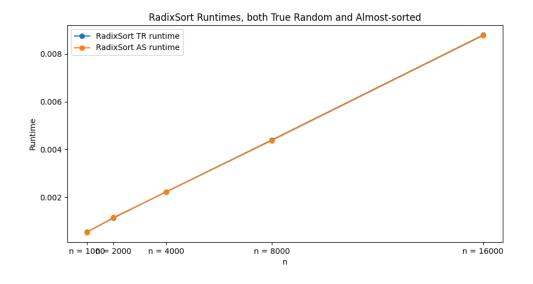

0.2.6 RadixSort Time Analysis

0.2.7 BinaryInsertionSort Time Analysis

I wrote the BinaryInsertionSort algorithm in an effort to improve runtime from the slow and clunky InsertionSort implementation(it appeared to be the slowest of our algorithms). After running InsertionSort and observing \sim 4 second runtimes on the larger data size(16000), I wanted to find an

approach that could drastically enhance its performance on large dataset sizes. I used two helper functions, one to perform the binary search to find the correct position to insert an element into the sorted subarray(binary_search()) and the other to execute the sorting logic in conjunction with the binary search mechanism(sort()). After completing my implementation for BinaryInsertionSort, both the truly random and almost sorted data of size 16000 saw immense improvements: roughly ~4 seconds runtimes on truly random and almost sorted data of size 16000 with InsertionSort to under 0.4 seconds with BinaryInsertionSort. BinaryInsertionSort roughly improved runtime from InsertionSort by around 90%. (Connor)

BinaryInsertionSort Natural Language PseudoCode:

Input: truly random generated array or almost sorted array of numbers Output: array in ascending order

```
1. (sort()) For each element (starting from the second element) in the array:
        1.a Set "current" to the element at the current index of the loop
        1.b Set "j" to a binary search() call to find the correct position to insert "curre
                1.bi (nested binary_search()) While the start index "start" is less than to
                        1.bi(a) Calculate the midpoint index "mid" by finding the halfway
                        1.bi(b) If the value of the midpoint "mid" is less than the target
                                1.bi(bi) Set the start index "start" to the midpoint plus
                        1.bi(c) Else:
                                1.bi(ci) Set the end index "end" to the midpoint index "mid
                1.bii Return the start index "start" as the position for which the "value"
        1.c Shift elements from "data" index "i - 1" to "j + 1" by one position to make ro
        1.d Place the "current" element at index "j" of "data"
```

- 2. Return the sorted array "data"
- Input for binary_search(): sorted array "data", value to be searched for "value" ("current" in sort()), start index of array "start", and end idex of array "end"
- Output for binary_search(): index where target value should be inserted

BinaryInsertionSort PsuedoCode:

```
class BinaryInsertionSort(CustomSort1):
    def __init__(self,):
        self.time = 0
    def binary_search(self, data to be sorted, target value for insertion, start index, end inc
        while start index < end index:
            midpoint index = (start index + end index) // 2
            if data to be sorted[midpoint index] < target value:</pre>
                start index = midpoint + 1
            else:
                end index = midpoint index
        return start index
    def sort(self, data to be sorted):
        for index i from 1 to length(data) - 1:
            current value = data to be sorted[ index i]
            index j = binary_search(data to be sorted, current value, 0, index i)
```

```
data to be sorted[index j + 1: index i + 1] = data to be sorted[index j:index i]
  data to be sorted[index j] = current value
return data sorted
```

Let's take a look at the runtime improvements from InsertionSort to BinaryInsertionSort.

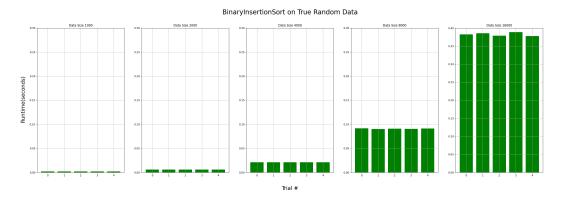

```
[]: bis_df = tr_df.loc[tr_df['Algo'] == 'Binary Insertion', ['Data Size', 'Observed_
     →Runtime']].copy()

                                                                     0.094617
    16000
                 0.382527
                                    3.863937
                                                                     0.098999
[]: bis_df = as_df.loc[as_df['Algo'] == 'Binary Insertion', ['Data Size', 'Observed_
     →Runtime']].copy()
    bis_df.rename(columns={'Observed Runtime': 'BIS Runtime'}, inplace=True)
    insertion_df = as_df.loc[as_df['Algo'] == 'Insertion', ['Data Size', 'Observed_
     →Runtime']].copy()
    insertion_df.rename(columns={'Observed Runtime': 'Insertion Runtime'},__
      →inplace=True)
    comparison_df = pd.merge(bis_df, insertion_df, on='Data Size')
    comparison_df['Runtime Ratio (BIS / Insertion)'] = comparison_df['BIS Runtime']_
      ⇔/ comparison_df['Insertion Runtime']
    comparison_df.set_index('Data Size', inplace=True)
```

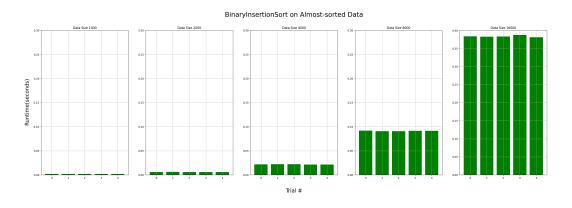

Comparison of BinaryInsertionSort to InsertionSort runtime on True Random data:

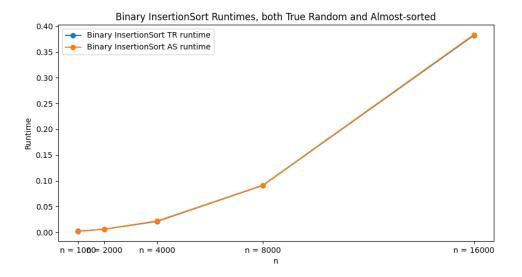

BIS Runtime Insertion Runtime Runtime Ratio (BIS / Insertion)

Data Size			
1000	0.001852	0.014492	0.127823
2000	0.005927	0.062298	0.095140
4000	0.021826	0.247955	0.088024
8000	0.091293	1.004275	0.090904
16000	0.383837	4.016604	0.095562

As we can see, these results clearly illustrate the substantial runtime improvements achieved by BinaryInsertionSort. Across both true random and almost sorted inputs, BinaryInsertionSort consistently demonstrated lower mean runtimes compared to InsertionSort. The above two tables show that as the size of the input data increases, the runtime ratio of BinaryInsertionSort to InsertionSort remains relatively stable, ranging from 0.09 to 0.13. These ratios reflect that BinaryInsertionSort improved run times by 88-92%. This illustrates how the combination of insertion sort and binary search is more efficient in terms of runtime than InsertionSort alone(regardless of the data size). By halving the search space with each comparison, it reduced the total number of comparisons needed to find the insertion index, thus leading to faster runtimes.

0.2.8 Simplified Timsort Time Analysis

Timsort was an appealing discovery during my research into iterative improvements upon these sorting algorithms, as Timsort's most robust and feature-complete version is actually used at the core of Python's built-in sort() and sorted() functions. I sought to duplicate at least some of its functionality - in particular, its utilization of building 'runs' with insertion sort, that are then brought together with mergesort. This 'run' component is the only aspect of its robustness I sought to integrate for performance gains in our relatively straightforward use case.

1 Timsort Pseudocode

```
Class Timsort: Initialize with some minimum length of each 'run': Set MIN RUN = 32
'sort' method, taking parameter 'data':
    Call recursive timsort_basic method, passing 'data'
    Return sorted 'data' upon completion of recursive sort
'timsort_basic' method with parameter 'data':
    Set 'n' to the length of 'data'
    Create runs of at least MIN_RUN size using 'insertion_sort'
    Initialize 'size' to MIN_RUN
    While 'size' is less than 'n' (merge the array, iteratively doubling the size of chunks to
        For each 'left' starting from 0, stepping by '2 * size':
            Calculate midpoint 'mid' as minimum of 'n - 1' and 'left + size - 1'
            Calculate 'right' as minimum of '(left + 2 * size - 1)' and '(n - 1)'
            If 'mid' is less than 'right', merge the current sections
        Double the 'size'
'insertion_sort' method with parameters 'data', 'left', 'right':
    For each position 'i' in range from 'left + 1' to 'right':
```

```
Initialize 'j' to 'i - 1'
            While 'j' is greater than or equal to 'left' and 'data[j]' is greater than 'key':
                Move 'data[j]' one position to the right
                Decrease 'j' by 1
            Place 'key' in the correct sorted position
    'merge' method with parameters 'data', 'left', 'mid', 'right':
        Initialize an empty list 'temp'
        Set 'i' to 'left' and 'j' to 'mid + 1'
        While either 'i' is less than or equal to 'mid' or 'j' is less than or equal to 'right':
            Compare elements from both halves and append the smaller one to 'temp'
            Increment 'i' or 'j' accordingly
        Append any remaining elements from either half to 'temp'
        Copy 'temp' back into 'data' starting from index 'left'
    Below, let's look at how this simplified timsort improves upon mergesort performance.
[]:|simple_tim_df = tr_df.loc[tr_df['Algo'] == 'Simple Tim', ['Data Size', __
      ⇔'Observed Runtime']].copy()
     simple_tim_df.rename(columns={'Observed Runtime': 'Simple Tim Runtime'},_

2 Simple Timsort Time Analysis

We can see that this simple implementation of Timsort provides a modest runtime improvement over MergeSort at the data sizes under consideration. While the performance delta is shrinking as n grows (from approximately a 20% improvement at n=1000, to a 12% improvement at n=16,000), this could be potentially be mitigated by adjusting Simple Timsort's starting size of calculated runs, perhaps seeding it as a log-base-two value that scales depending on n. We also see that Timsort is one of the algorithms that suffers a performance hit when working with almost-sorted data, likely derived from the fact that it uses insertion sort as one of its internal mechanisms.

2.1 Comparative Time Analysis

For our comparative time analysis, let's bring in some code and import results.

3 Ranking Table, per data size: True Random permutations

```
[]: data_sizes = tr_df['Data Size'].unique()
     # Prepare an empty dict to hold the algorithms and their runtimes for each data_
     rankings_with_runtime = {}
     for size in data sizes:
         # Filter rows matching current 'Data Size'
         filtered df = tr df[tr df['Data Size'] == size]
         filtered_df = filtered_df.sort_values(by='Observed Runtime')
         # Combine 'Algo' and 'Observed Runtime' into a single string for each row
         combined_info = filtered_df.apply(lambda x: "{} ({:.6f}s)".

→format(x['Algo'], x['Observed Runtime']), axis=1).values

         sorted_by_runtime = filtered_df.sort_values(by='Observed_
      →Runtime')['Observed Runtime'].values
         sorted_combined_info = [info for _,info in sorted(zip(sorted_by_runtime,_
      ⇔combined info))]
         rankings_with_runtime[size] = sorted_combined_info
     max_length = max(len(v) for v in rankings_with_runtime.values())
     for size in rankings with runtime:
         rankings_with_runtime[size] = list(rankings_with_runtime[size]) + [None] *__
      ⇔(max_length - len(rankings_with_runtime[size]))
     tr_ranked_with_runtime_df = pd.DataFrame(rankings_with_runtime)
     tr_ranked_with_runtime_df.index += 1 # Ranking starts from 1
     print("True Random execution time rankings, per data size.")
     print(tr_ranked_with_runtime_df)
```

True Random execution time rankings, per data size.

5 Observations regarding rankings, patterns, performance as n changes.

- A few things across the rankings are constant:
 - Bucket and Radix hold the #1 and #2 spot consistently across all data sizes and across both permutation styles. Very fast.
 - Conversely, Shell (7-3-1) and Insertion sort occupy the bottom of the field #8 and #9
 across all data sizes and permutation styles
 - Insertion's lack of speed is demonstrating itself dramatically as n increases.
- Other notes:
 - Quicksort begins faster than Simple Tim and Mergesort at n=1000, but by $n=16{,}000$ both of the latter are running faster.
 - Simple Tim seems to cope the best with growing datasize, even in its primitive implementation, compared to rote Quick and Mergesort.
 - Similarly, as data size grows, Shellsort (1000 100 10 1) steals Binary Insertion's #6 rank. As n increases, there seems to be some risk of Binary Insertion dramatically increasing in execution speed sensible, as an O(n^2) algorithm.

8 Common Big-O Functions for Each Algorithm, Based On Observed Empiricial Asymptotic Runtime Using Doubling Hypothesis

Note: For these assignments, we're using the doubling hypothesis factor guidelines provided on Edstem and our own judgement based on the trend of observed runtime ratio as data size changes for each algorithm.

- Merge: Ratio of approximately 1 through 1.1. Assigning O(log (n)).
- Quick: Ratio of approximately 1.15 through 1.3, growing as n increases. Assigning O(n).
- Insertion: Ratio of approximately 2. Assigning $O(n \log(n))$.
- Shell (7-3-1): Ratio of approximately 1.95. Assigning O(n log(n)).
- Shell (1000-100-10-1): Ratio of approximately 1.58 to 1.46, decreasing. Assigning O(n).
- Bucket: Ratio of approximately 0.7 0.9. Assigning $O(\log(n))$.
 - Note: There was an extreme result in our initial data states that resulted in a peculiar value for the third seed under the true random permutation case. As such, we have a negative ratio. Given Bucket's consistency across every other trial, we are making this assignment by analyzing those trials primarily. We found it amusing to strike such a strange result, and decided to keep it in instead of shuffling our seeding arrangement to sidestep it, given the algorithm reliably sorts.
- Radix: Ratio of approximately 0.95 1.1. Assigning O(log (n)).
- Binary Insertion: Ratio of approximately 1.65 at n = 1000, to 2.1 as n increases. Given this progressive delta, assigning O(n).
- Simplified Tim: Ratio of approximately 1.15 to 1.1, shrinking as n increases. Assigning $O(\log(n))$.

9 Noted Differences Between Observed Runtime Versus Theoretical Big-O Runtime

For these comparisons, we're using Big-O time complexity for each algorithm that considers their worst case scenario.

- Merge: Assigned $O(\log(n))$, worst case $O(n \log(n))$. Based on the doubling hypothesis factor, in practice this was faster than linearithmic.
- Quick: Assigned O(n), given its ratio grew as data size increased. Worst case O(n^2). Again, this was much faster than its worst-case Big-O. This is also appreciably faster than its average case Big-O, O(n log(n)).
- Insertion: Assigned O(n log(n)). Reliably right around 2, dithering as data increased. Faster in practice than its worst-case O(n^2) with these data, but quite slow to begin with compared to the competition.
- Shell: We see appreciable differences in the gap assignment between the two Shell schemas provided. (7-3-1)'s ratio held near 2, and was assigned O(n log(n)), while (1000-100-10-1) steadily decreased, and was assigned O(n). A clear case for how the Shell gap schema and data size interact to determine sorting speed relative to Shell's worst-case, O(n^2)
- Bucket: So fast. Assigned O(log(n)). Steadily beneath 1, suggesting that it was getting relatively faster as the data size increased. Likely due to the fact that as n increased, the numer of possible buckets never changed it was always 1000. Interesting, and clearly ahead

- of its O(n) theoretical runtime in practice.
- Radix: Ratio around 1, dithering, assigned $O(\log(n))$. Almost as fast as bucket; begs inquiry into what relationship between n-tuple wordsize or bucket count necessitates a switch from one to the other. Outperformed worst-case O(nd).
- Binary Insertion: Clear improvement from Insertion, but its ratios were slightly higher than Insertion as data size increased. This may suggest that in huge datasets, regular Insertion catches up. Assigned O(n), performing ahead of its O(n^2) worst-case.
- Timsort: Satisfying combination that takes advantage of the strengths of Insertion and Merge. Pulled ahead of everything non-Bucket/Radix at n = 16,000. Assigned $O(\log(n))$, better than its worst case of $O(\log(n))$.
